# Unicorn

### Installation

### Install Unicorn

Install Unicorn the same as any other Python package (preferably into a virtual environment).

```
pip install django-unicorn
```

OR

```
poetry add django-unicorn
```

### Note

If attempting to install django-unicorn and orjson is preventing the installation from succeeding, check whether it is using 32-bit Python. Unfortunately, orjson is only supported on 64-bit Python. More details in issue #105.

# Integrate Unicorn with Django

1. Add "django\_unicorn", to the INSTALLED\_APPS array in the Django settings file (normally settings.py)

```
# settings.py
INSTALLED_APPS = (
    # other apps
    "django_unicorn",
)
```

2. Add path("unicorn/", include("django\_unicorn.urls")), into the project'surls.py

```
# urls.py
urlpatterns = (
    # other urls
    path("unicorn/", include("django_unicorn.urls")),
)
```

- 3. Add {% load unicorn %} to the top of the Django HTML template
- 4. Add {% unicorn\_scripts %} and {% csrf\_token %} into a Django HTML template

Then, create a component.

# Components

Unicorn uses the term "component" to refer to a set of interactive functionality that can be put into templates. A component consists of a Django HTML template with specific tags and a Python class which provides the backend code for the template.

### Create a component

The easiest way to create your first component is to run the following Django management command after Unicorn is installed.

python manage.py startunicorn hello-world

## Warning

If this is the first component you create, you will also need to add "unicorn", to INSTALLED\_APPS in your Django settings file (normally settings.py) to make sure that Django can find the created component templates.

Also, make sure that there is a {% csrf\_token %} in your HTML somewhere to prevent cross-site scripting attacks while using Unicorn.

### Note

Change which apps Unicorn looks in for components with the APPS setting.

Add {% unicorn 'hello-world' %} into the template where you want to load the new component.

# Component key

If there are multiple of the same components on the page, a key kwarg can be passed into the template. For example, {% unicorn 'hello-world' key='helloWorldKey' %}.

# Component arguments

kwargs can be passed into the unicorn templatetag from the template. The kwargs will be available in the component \_\_init\_\_ method.

# Warning

When overriding \_\_init\_\_ calling super().\_\_init\_\_(\*\*kwargs) is required for the component to initialize properly.

```
# hello_world.py
from django_unicorn.components import UnicornView

class HelloWorldView(UnicornView):
    name = "World"

def __init__(self, *args, **kwargs):
    super().__init__(**kwargs) # calling super is required
    self.name = kwargs.get("name")
```

```
<!-- index.html -->
{% unicorn 'hello-world' name="Universe" %}
```

Regular Django template variables can also be passed in as an argument as long as it is available in the template context.

```
# views.py
from django.shortcuts import render

def index(request):
    context = {"hello": {"world": {"name": "Galaxy"}}}
    return render(request, "index.html", context)

<!-- index.html -->
{% unicorn 'hello-world' name=hello.world.name %}
```

## Example component

A basic example component could consist of the following template and class.

```
# hello_world.py
from django_unicorn.components import UnicornView

class HelloWorldView(UnicornView):
name = "World"
```

unicorn:model is the magic that ties the input to the backend component. The Django template variable can use any property or method on the component as if they were context variables passed in from a view. The attribute passed into unicorn:model refers to the property in the component class and binds them together.

#### Note

By default unicorn:model updates are triggered by listening to input events on the element. To listen for the blur event instead, use the lazy modifier.

When a user types into the text input, the information is passed to the backend and populates the component class, which is then used to generate the output of the template HTML. The template can use any normal Django templatetags or filters (e.g. the title filter above).

#### Unicorn attributes

Attributes used in component templates usually start with unicorn:, however the shortcut u: is also supported. So, for example, unicorn:model could also be written as u:model.

# Supported property types

Properties of the component can be of many different types, including str, int, list, dictionary, Django Model, Django QuerySet, Or custom classes.

#### Accessing nested fields

Fields in a dictionary or Django model can be accessed similarly to the Django template language with "dot-notation".

```
# hello_world.py
from django_unicorn.components import UnicornView
from book.models import Book

class HelloWorldView(UnicornView):
    book = Book.objects.get(title='American Gods')
    book_ratings = {'excellent': {'title: 'American Gods'}}

<!-- hello-world.html -->
<div>
    <input unicorn:model="book.title" type="text" id="model" />
    <input
    unicorn:model="book_ratings.excellent.title"
    type="text"
    id="dictionary"
    />
```

#### Note

</div>

Django models has many more details about using Django models in Unicorn.

### Django QuerySet

Django QuerySet can be referenced similarly to the Django template language in a unicorn: model.

```
# hello_world.py
from django_unicorn.components import UnicornView
from book.models import Book

class HelloWorldView(UnicornView):
books = Book.objects.all()
```

#### Note

Django models has many more details about using Django QuerySets in Unicorn.

#### Custom class

Custom classes need to define how they are serialized. If you have access to the object to serialize, you can define a to\_json method on the object to return a dictionary that can be used to serialize. Inheriting from unicorn.components.UnicornField is a quick way to serialize a custom class, but note that it just calls self.\_\_dict\_\_ under the hood, so it is not doing anything particularly smart.

Another option is to set the form\_class on the component and utilize Django's built-in forms and widgets to handle how the class should be deserialized. More details are provided in validation.

```
# hello_world.py
from django_unicorn.components import UnicornView, UnicornField
```

```
class Author(UnicornField):
    def __init__(self):
        self.name = 'Neil Gaiman'

# Not needed because inherited from `UnicornField`
    # def to_json(self):
    # return {'name': self.name}

class HelloWorldView(UnicornView):
        author = Author()
```

### !DANGER!

Never put sensitive data into a public property because that information will publicly available in the HTML source code.

# **Templates**

Templates are just normal Django HTML templates, so anything you could normally do in a Django template will still work, including template tags, filters, loops, if statements, etc.

## Warning

Unicorn requires there to be one root element surrounding the component template.

### Model modifiers

### Lazy

To prevent updates from happening on *every* input, you can append a lazy modifier to the end of unicorn:model. That will only update the component when a blur event happens.

#### **Debounce**

The debounce modifier configures how long to wait to fire an event. The time is always specified in milliseconds, for example: unicorn:model.debounce-1000 would wait for 1000 milliseconds (1 second) before firing the message.

#### Defer

The defer modifier will store and save model changes until the next action gets triggered. This is useful to prevent additional network requests until an action is triggered.

### **Chaining modifiers**

Lazy and debounce modifiers can even be chained together.

## Key

### Smooth updates

Setting a unique id on elements with unicorn:model will prevent changes to an input from being choppy when there are lots of updates in quick succession.

```
<!-- choppy-updates.html -->
<input type="text" unicorn:model="name"></input>

!-- smooth-updates.html -->
<input type="text" id="someFancyId" unicorn:model="name"></input>
```

However, setting the same id on two elements with the same unicorn: model won't work. The unicorn: key attribute can be used to make sure that the elements can be synced as expected.

```
<!-- missing-updates.html -->
<input type="text" id="someFancyId" unicorn:model="name"></input>
<input type="text" id="someFancyId" unicorn:model="name"></input>
cinput type="text" id="someFancyId" unicorn:model="name"></input>
```

```
<!-- this-should-work.html -->
<input type="text" id="someFancyId" unicorn:model="name"></input>
<input type="text" id="someFancyId" unicorn:model="name" unicorn:key="someFancyKey"></input>
```

### **DOM merging**

The JavaScript library used to merge changes in the DOM, morphdom, uses an element's id to intelligently update DOM elements. If it isn't possible to have an id attribute on the element, unicorn: key will be used if it is available.

# **Child components**

Unicorn supports nesting components so that one component is a child of another. Since HTML is a tree structure, a component can have multiple children, but each child only has one parent.

We will slowly build a nested component example with three components: table, filter and row. The table is the parent and contains the other two components. The filter will update the parent table component, and the row will contain functionality to edit a row.

## Parent component

So that Unicorn knows about the parent-child relationship, the child component must pass in a parent keyword argument with the parent's component view.

```
<!-- table.html -->
{% load unicorn %}
<div>
 {% unicorn 'filter' parent=view %}
 <thead>
    Author
     Title
    </thead>
   {% for book in books %}
  {{ book.author }}
    {{ book.title }}
  {% endfor %}
 </div>
```

```
# table.py
from book.models import Book
from django_unicorn.components import UnicornView

class TableView(UnicornView):
   books = Book.objects.none()

   def mount(self):
       self.load_table()

   def load_table(self):
       self.books = Book.objects.all()[0:10]
```

# Child component

def updated\_search(self, query):

The child filter component, {% unicorn 'filter' parent=view %}, will have access to its parent through the view's self.parent. The FilterView is using the updated method to filter the books queryset on the table component when the filter's search model is changed.

```
self.parent.load_table()

if query:
    self.parent.books = list(
        filter(lambda f: query.lower() in f.title.lower(), self.parent.books)
)
```

## Multiple children

If we want to encapsulate the editing and saving of a row of data, we can add in a row component as well.

```
<!-- row.html -->
>
   {% if is_editing %}
   <input type="text" unicorn:model.defer="book.author" />
    {% else %}
    {{ book.author }}
    {% endif %}
 >
    {% if is_editing %}
   <input type="text" unicorn:model.defer="book.title" />
    {% else %}
    {{ book.title }}
    {% endif %}
 >
    {% if is_editing %}
   <button unicorn:click="save">Save</button>
   <button unicorn:click.discard="cancel">Cancel</button>
    {% else %}
   <button unicorn:click="edit">Edit</button>
   {% endif %}
```

```
# row.py
from django_unicorn.components import UnicornView

class RowView(UnicornView):
   book = None
   is_editing = False

   def edit(self):
       self.is_editing = True

   def cancel(self):
       self.is_editing = False

   def save(self):
       self.book.save()
       self.is_editing = False
```

The changes for the table component where the row child component is added in. Views will always have a children attribute – here it is used to set is\_editing to false on all rows when the table gets reloaded.

```
<!-- table.html --->
{% load unicorn %}
<div>
    {% unicorn 'filter' parent=view %}
```

```
<thead>

Author
Author

Title
```

# Warning

Unicorn requires components to have a unique identifier. Normally that is handled automatically, however multiple child components with the same component name require some help.

For child components, unicorn:id is automatically created from the parent's unicorn:id and the child's component name. If a child component is created multiple times in the same parent, one of the following can be used to create unique identifiers:

```
• pass in a key keyword argument to the child component

{% unicorn 'row' parent=view book=book key=book.id %}

• pass in an id keyword argument to the child component

{% unicorn 'row' parent=view book=book id=book.id %}

• the view has an attribute named model which has either a pk or id attribute

{% unicorn 'row' parent=view model=book %}
```

# **Django Models**

Unicorn provides tight integration with Django Models and Querysets to handle typical Django workflows. There are multiple ways to integrate a Django model with a component. They all work a little differently and which option you choose to use depends on the situation.

### **DbModel**

One way to use Django models is by utilizing the DbModel class that provides a way from the front-end to refer to a Django model. The value of the unicorn: db attribute refers to the first argument when constructing a DbModel and unicorn: field is used for the model's field that should be bound to the input.

Another benefit of DbModel is that it enables the use of the \$model special action variable.

```
# db_model.py
from django_unicorn.components import UnicornView
from django_unicorn.db import DbModel
from books.models import Book

class DbModelView(UnicornView):
    class Meta:
        db_models = [DbModel("book", Book)]

def save(self):
        print("A new book will be created automatically")
        pass
```

unicorn:db can also live in a parent element and surround a group of unicorn:field inputs.

unicorn:pk can be used so that an existing model is updated instead of a new model is created. More information about unicorn:pk is in queryset.

### Class Model

Django models can be initialized similar to how basic Python objects (i.e. strings, integers, dictionaries) can be set on a component.

```
# class_model.py
from django_unicorn.components import UnicornView
from books.models import Book

class ClassModelView(UnicornView):
    book = Book()

    def save(self):
        self.book.save()
```

### Instance Model

Django models can be initialized in the component's \_\_init\_\_ method similar to how a "normal" class would initialize an instance variable.

### !DANGER!

super().\_\_init\_\_(\*\*kwargs) has to be called at the end of the overriden \_\_init\_\_ method.

```
# instance_model.py
from django_unicorn.components import UnicornView
from books.models import Book

class InstanceModelView(UnicornView):
    def __init__(self, **kwargs):
        self.book = Book()

    # super() has to be called at the end
        super().__init__(**kwargs)
```

```
def save(self):
    self.book.save()
```

### **Queryset**

Binding models to a Django Queryset is done by setting an unicorn:pk attribute with the model's pk (normally an integer in an id field, but could be a custom primary\_key).

## Warning

A blank value for an unicorn:pk attribute signals to Unicorn to create a new instance of the underlying Django model of the queryset.

```
<!-- queryset.html -->
<div>
  <div unicorn:model="books">
   <div unicorn:pk="">
      <!-- A blank pk will create a new model when it is saved -->
        <input unicorn:field.defer="title" type="text" id="title" />
      </div>
      <div>
        <input unicorn:field.defer="description" type="text" id="description" />
      </div>
    </div>
    {% for book in books %}
   <div unicorn:pk="{{ book.pk }}">
      <!-- Using the model's pk will save the model -->
        <input unicorn:field.defer="title" type="text" id="title" />
        {{ book.title }}
      </div>
      <div>
        <input unicorn:field.defer="description" type="text" id="description" />
        {{ book.description }}
      </div>
   </div>
    {% endfor %}
  </div>
  <button unicorn:click="save">Save</button>
</div>
```

```
# queryset.py
from django_unicorn.components import UnicornView
from books.models import Book

class QuerysetView(UnicornView):
books = Book.objects.none()

def hydrate(self):
    # Using `hydrate` is the best way to make sure that QuerySets
    # are re-queried every time the component is loaded
    self.books = Book.objects.all().order_by("-id")[:5]

def save(self):
    pass
```

### **Actions**

Components can also trigger methods from the templates by listening to any valid event type. The most common events would be click, input, keydown, keyup, and mouseenter, but MDN has a list of all of the browser event types available.

### **Events**

An example action to call the clear\_name method on the component.

```
# clear_name.py
from django_unicorn.components import UnicornView

class ClearNameView(UnicornView):
    name = "World"

def clear_name(self):
    self.name = ""
```

When the button is clicked, the name property will get set to an empty string. Then, the component will intelligently re-render itself and the text input will update to match the property on the component.

## **Tip**

Instance methods without arguments can be called from the template with or without parenthesis.

# Passing arguments

Actions can also pass basic Python types to the backend component.

```
# passing_args.py
from django_unicorn.components import UnicornView

class PassingArgsView(UnicornView):
    name = "World"

def set(self, name="Universe"):
    self.name = name
```

#### Argument types

Arguments can be most basic Python types, including string, int, float, list, tuple, dictionary, set, datetime, and UUID4.

### Note

Strings will be converted to datetime if they are successfully parsed by Django's parse\_datetime method.

### Set shortcut

Actions can also set properties without requiring an explicit method.

#### **Modifiers**

Similar to models, actions also have modifiers which change how the method gets called.

#### prevent

Prevents the default action the browser would use for that element. The same as calling preventDefault.

### stop

Stops the event from bubbling up the event chain. The same as calling stopPropagation.

### discard

Discards any model updates from being saved before calling the specified method on the view. Useful for a cancel button.

### Special arguments

pass

### \$event

A reference to the event that triggered the action.

### \$model

Sends the current db\_model to an action.

#### Note

\$model requires db\_models to be defined in the component's Meta class. The component method must also be decorated with django\_unicorn.decorators.db\_model and must have at least one argument (which will be converted into the specified Django model from the frontend).

```
# model.py
from django_unicorn.components import UnicornView
from django_unicorn.db import DbModel
from django_unicorn.decorators import db_model
from .models import Book

class ModelView(UnicornView):
   books = Book.models.all()

@db_model
   def delete(self, book):
        book.delete()

class Meta:
        db_models = [DbModel("book", Book)]
```

```
<!-- model.html -->
<div>
```

### \$returnValue

A reference to the last return value from an action method.

# Special methods

#### \$refresh

Refresh and re-render the component from its current state.

#### \$reset

Revert the component to its original state.

### \$toggle

Toggle a field on the component. Can only be used for fields that are booleans.

### Tip

Multiple fields can be toggled at the same time by passing in multiple fields at a time: unicorn:click="\$toggle('check', 'another\_check', 'a\_third\_check')". Nested properties are also supported: unicorn:click="\$toggle('nested.check')".

#### \$validate

Validates the component.

## **Calling methods**

Sometimes you need to trigger a method on a component from regular JavaScript. That is possible with Unicorn.call(). It can be called from anywhere on the page.

```
<!-- index.html -->
{% unicorn 'hello-world' %}

<button onclick="Unicorn.call('hello-world', 'set_name');">
   Set the name from outside the component
</button>
```

### Return values

To retrieve the last action method's return value, use Unicorn.getReturnValue().

```
<!-- index.html -->
{% unicorn 'hello-world' %}

<button onclick="alert(Unicorn.getReturnValue('hello-world'));">
   Get the last return value
</button>
```

### **Validation**

Unicorn uses Django forms infrastructure for all validation. This means that a form could be re-used between any other Django views and a Unicorn.

Using the Django forms system provides a way to serialize/deserialize certain classes (for example, datetime and uuid) and a way to validate properties of a class.

### Note

There are many built-in fields available for Django form fields which can be used to validate text inputs.

```
# book.py
from django_unicorn.components import UnicornView
from django import forms

class BookForm(forms.Form):
    title = forms.CharField(max_length=100, required=True)
    publish_date = forms.DateField(required=True)

class BookView(UnicornView):
    form_class = BookForm

    title = ""
    publish_date = ""
```

Because of the form\_class = BookForm defined on the UnicornView above, Unicorn will automatically validate that the title has a value and is less than 100 characters. The publish\_date will also be converted into a datetime from the string representation in the text input.

## Showing validation errors

As the form is filled out the appropriate inputs will be validated. There are a few ways to show the validation messages.

### Highlighting the invalid form

When a model form is invalid, a special unicorn: error attribute is added to the element. Depending on whether it is an invalid or required error code, the attribute will be unicorn: error: invalid or unicorn: error: required. The value of the attribute will be the validation message.

### Showing a specific error message

### Showing all the error messages

There is a unicorn\_errors template tag that shows all errors for the component. It should provide an example of how to display component errors in a more specific way if needed.

```
<!-- show-all-error-messages.html -->
{% load unicorn %}

<div>
    {% unicorn_errors %}

    <input unicorn:model="publish_date" type="text" id="publish-date" /><br />
</div>
```

# Validate the entire component

The magic action method \$validate can be used to validate the whole component by the front-end.

The validate method can also be used inside of the component.

```
# validate.py
from django_unicorn.components import UnicornView
from django import forms

class BookForm(forms.Form):
    title = forms.CharField(max_length=6, required=True)

class BookView(UnicornView):
    form_class = BookForm

    text = "hello"

def set_text(self):
    self.text = "hello world"
    self.validate()
```

The is\_valid can also be used inside of the component to check if a component is valid.

```
# validate.py
from django_unicorn.components import UnicornView
from django import forms

class BookForm(forms.Form):
    title = forms.CharField(max_length=6, required=True)

class BookView(UnicornView):
    form_class = BookForm

    text = "hello"

def set_text(self):
    if self.is_valid():
        self.text = "hello world"
```

# Redirecting

Unicorn has a few different ways to redirect from an action method.

#### Redirect

To redirect the user, return a HttpResponseRedirect from an action method. Using the Django shortcut redirect method is one way to do that in a typical Django manner.

#### Note

django.shortcuts.redirect can take a Django model, Django view name, an absolute url, or a relative url. However, the permanent kwarg for redirect has no bearing in this context.

# **Tip**

It is not required to use django.shortcuts.redirect. Anything that returns a HttpResponseRedirect will behave the same in Unicorn.

```
# redirect.py
from django.shortcuts import redirect
from django_unicorn.components import UnicornView
from .models import Book

class BookView(UnicornView):
    title = ""

    def save_book(self):
        book = Book(title=self.title)
        book.save()
        self.reset()

    return redirect(f"/book/{book.id}")
```

## HashUpdate

To avoid a server-side page refresh and just update the hash at the end of the url, return HashUpdate from the action method.

```
# hash_update.py
from django_unicorn.components import HashUpdate, UnicornView
from .models import Book

class BookView(UnicornView):
   title = ""

   def save_book(self):
       book = Book(title=self.title)
       book.save()
       self.reset()

   return HashUpdate(f"#{book.id}")
```

# LocationUpdate

To avoid a server-side page refresh and update the whole url, return a LocationUpdate from the action method. LocationUpdate is instantiated with a HttpResponseRedirect arg and an optional title kwarg.

### Note

LocationUpdate uses window.history.pushState so the new url must be relative or the same origin as the original url.

```
# location_update.py
from django.shortcuts import redirect
from django_unicorn.components import LocationUpdate, UnicornView
from .models import Book

class BookView(UnicornView):
    title = ""

    def save_book(self):
        book = Book(title=self.title)
        book.save()
        self.reset()

    return LocationUpdate(redirect(f"/book/{book.id}}"), title=f"{book.title}")
```

# **Loading States**

Because Unicorn requires an AJAX request for any component updates, it is helpful to provide some context to the user that an action is happening.

# **Toggling Elements**

Elements with the unicorn: loading attribute are only visible when an action is in process.

When the *Update* button is clicked, the "Updating!" message will show until the action is complete, and then it will re-hide itself.

# Warning

Loading elements get shown or removed with the hidden attribute. One drawback to this approach is that setting the style display property overrides this functionality.

You can also hide an element while an action is processed by adding a remove modifier.

```
<div unicorn:loading.remove>Not currently updating!</div>
</div>
```

If there are multiple actions that happen in the component, you can show or hide a loading element for a specific action by targetting another element's id with unicorn: target.

An element's unicorn: key can also be targeted.

# **Toggling Attributes**

Elements with an action event can also include an unicorn:loading attribute with either an attr or class modifier.

### attr

Set the specified attribute on the element that is triggering the action.

This example will disable the *Update* button when it is clicked and remove the attribute once the action is completed.

### class

Add the specified class to the element that is triggering the action.

This example will add a loading class to the *Update* button when it is clicked and remove the class once the action is completed.

#### class.remove

Remove the specified class from the element that is triggering the action.

This example will remove a active class from the *Update* button when it is clicked and add the class back once the action is completed.

```
Update
  </button>
  </div>
```

# **Polling**

unicorn:poll can be added to the root div element of a component to have it refresh the component automatically every 2 seconds. The polling is smart enough that it won't poll when the page is inactive.

```
# polling.py
from django.utils.timezone import now
from django_unicorn.components import UnicornView

class PollingView(UnicornView):
    current_time = now()
```

```
<!-- polling.html -->
<div_unicorn:poll>{{ current_time }}</div>
```

A method can also be specified if there is a specific method on the component that should called every time the polling fires. For example, unicorn:poll="get\_updates" would call the get\_updates method instead of the built-in refresh method.

To define a different refresh time in milliseconds, a modifier can be added as well. unicorn:poll-1000 would fire the refresh method every 1 second, instead of the default 2 seconds.

# Disable poll

Polling can dynamically be disabled by checking a boolean field from the component.

```
# poll_disable.py
from django.utils.timezone import now
from django_unicorn.components import UnicornView

class PollDisableView(UnicornView):
   polling_disabled = False
   current_time = now()

def get_date(self):
    self.current_time_= now()
```

#### Note

The field passed into unicorn:poll.disable can be negated with an exclamation point.

```
# poll_disable_negation.py
from django.utils.timezone import now
```

```
from django_unicorn.components import UnicornView

class PollDisableNegationView(UnicornView):
    polling_enabled = True
    current_time = now()

def get_date(self):
    self.current_time = now()

<!-- poll-disable-negation.html -->
    <div unicorn:poll-1000="get_date" unicorn:poll_disable="!polling_enabled">
        current_time: {{ current_time|date:"s" }} <br/>
        <button u:click="$toggle('polling_enabled')">Toggle Polling</button>
    </div>
```

## **PollUpdate**

A poll can be dynamically updated by returning a PollUpdate object from an action method. The timing and method can be updated, or it can be disabled.

```
# poll_update.py
from django.utils.timezone import now
from django_unicorn.components import PollUpdate, UnicornView

class PollingUpdateView(UnicornView):
    polling_disabled = False
    current_time = now()

def get_date(self):
    self.current_time = now()
    return PollUpdate(timing=2000, disable=False, method="get_date")
```

```
<!-- poll-update.html -->
<div unicorn:poll-1000="get_date">
    current_time: {{ current_time|date:"s" }}<br />
</div>
```

### **Advanced**

# Class properties

#### template\_name

By default, the component name is used to determine what template should be used. For example, hello\_world.HelloWorldView would by default use unicorn/hello-world.html. However, you can specify a particular template by setting template\_name in the component.

```
# hello_world.py
from django_unicorn.components import UnicornView

class HelloWorldView(UnicornView):
    template_name = "unicorn/hello-world.html"
```

### Instance properties

### request

The current request is available on self in the component's methods.

```
# hello_world.py
from django_unicorn.components import UnicornView

class HelloWorldView(UnicornView):
    def __init__(self, *args, **kwargs):
        super.__init__(**kwargs)
        print("Initial request that rendered the component", self.request)

def test(self):
    print("callMethod request to re-render the component", self.request)
```

### Custom methods

Defined component instance methods with no arguments are made available to the Django template context and can be called like a property.

```
# states.py
from django_unicorn.components import UnicornView

class StateView(UnicornView):
    def all_states(self):
        return ["Alabama", "Alaska", "Arizona", ...]
```

### Tip

If the method is intensive and will be called multiple times, it can be cached with Django's <a href="https://docs.djangoproject.com/en/stable/ref/utils/#django.utils.functional.cached\_property">cached\_property</a> to prevent duplicate API requests or database queries. The method will only be executed once per component rendering.

```
# states.py
from django.utils.functional import cached_property
from django_unicorn.components import UnicornView

class StateView(UnicornView):
    @cached_property
    def all_states(self):
        return ["Alabama",_"Alaska",_"Arizona", ...]
```

### Instance methods

### \_init\_\_()

Gets called when the component gets constructed for the very first time. Note that constructed components get cached to reduce the amount of time discovering and instantiating them, so \_\_init\_\_ only gets called the very first time the component gets rendered.

```
# hello_world.py
from django_unicorn.components import UnicornView

class HelloWorldView(UnicornView):
    name = "original"

def __init__(self, *args, **kwargs):
    super().__init__(**kwargs)
    self.name = "initialized"
```

### mount()

Gets called when the component gets initialized or reset.

```
# hello_world.py
from django_unicorn.components import UnicornView

class HelloWorldView(UnicornView):
    name = "original"

def mount(self):
    self.name = "mounted"
```

### hydrate()

Gets called when the component data gets set.

```
# hello_world.py
from django_unicorn.components import UnicornView

class HelloWorldView(UnicornView):
    name = "original"

def hydrate(self):
    self.name = "hydrated"
```

### updating(name, value)

Gets called before each property that will get set.

### updated(name, value)

Gets called after each property gets set.

### updating\_{property\_name}(value)

Gets called before the specified property gets set.

### updated\_{property\_name}(value)

Gets called after the specified property gets set.

### calling(name, args)

Gets called before each method that gets called.

### called(name, args)

Gets called after each method gets called.

#### Meta

Classes that derive from UnicornView can include a Meta class that provides some advanced options for the component.

#### exclude

By default, all properties of the component are included in the payload when hydrating the Django template. One way to prevent internal-only data from getting POSTed needlessly is to prefix the property name with \_ to indicate it should stay private.

```
# hello_state.py
from django_unicorn.components import UnicornView

class HelloStateView(UnicornView):
    state = ""

    _all_states = (
        "Alabama",
        "Alaska",
        "Arizona",
        "Arkansas",
        ...
        "Wisconsin",
        "Wyoming",
    )
}
```

Another way to prevent that data from going across the wire on every interaction is to add it to the Meta class's exclude tuple.

```
# hello_state.py
from django_unicorn.components import UnicornView

class HelloStateView(UnicornView):
    state = ""

    all_states = (
        "Alabama",
        "Alaska",
        "Arizona",
        "Arkansas",
        ...
        "Wisconsin",
        "Wyoming",
    )

    class Meta:
        exclude = ("all_states", )
```

# **Settings**

Unicorn stores all settings in a dictionary under the DJANGO\_UNICORN setting attribute in the Django settings file. All settings are optional.

```
# settings.py
DJANGO_UNICORN = {
    "MINIMIZE": True,
    "APPS": ["unicorn"]
}
```

### **MINIMIZE**

Provides a way to control if the minimized version of unicorn.min.js is used. Defaults to !DEBUG.

#### **APPS**

Specify the modules to look for components. Defaults to ["unicorn",].

# CLI

Unicorn provides a Django management command to create new components.

```
python manage.py startunicorn hello-world
```

The command will create a unicorn directory, and templates and components sub-directories if necessary. Underneath the components directory there will be a new module and subclass of django\_unicorn.components.UnicornView. Underneath the templates/unicorn directory will be a example template.

The following is an example folder structure.

```
unicorn/
    components/
    hello_world.py
    templates/
    unicorn/
    hello-world.html
```

# Changelog

### v0.15.1

• Fix bug where a component name has a dash in its name

All changes since 0.15.1.

#### v0.15.0

- · Add support for child components
- · Add discard action modifier
- Add support for referring to components in a folder structure
- Remove restriction that component templates must start with a div
- Remove restriction that component root can't also have unicorn:model or unicorn:action

All changes since 0.15.0.

### v0.14.1

• Prevent the currently focused model element from updating after the AJAX request finishes (#100).

All changes since 0.14.0.

### v0.14.0

- Disable poll with a component field
- Dynamically change polling options with PollUpdate
- Basic support for pydantic models

All changes since 0.13.0.

### v0.13.0

- Component key to allow disambiguation of components of the same name
- \$returnValue special argument
- · Get the last action method's return value

All changes since 0.12.0.

### v0.12.0

· Redirect from action method in component

All changes since 0.11.2.

### v0.11.2

- Fix encoding issue with default component template on Windows (#91)
- Fix circular import when creating the component (#92)

All changes since 0.11.0.

### v0.11.0

- \$model special argument and decorator.
- \$toggle special method.
- Support nested properties when using the set shortcut.
- Fix action string arguments that would get spaces removed inadvertently.

### **Breaking changes**

• All existing special methods now start with a \$ to signify they are magical. Therefore, refresh is now \$refresh, reset is now \$reset, and validate is now \$validate.

All changes since 0.10.1.

### v0.10.1

- Use LRU cache for constructed components to prevent ever-expanding memory.
- Loosen beautifulsoup4 version requirement.
- Fix bug to handle floats so that they don't lose precision when serialized to JSON.
- Fix bug to handle related models (ForeignKeys, OneToOne, etc) fields in Django models.

All changes since 0.10.0.

### v0.10.0

- Add support for passing kwargs into the component on the template
- Provide access to the current request in the component's methods

All changes since 0.9.4.

### v0.9.4

- Fix: Prevent Django CharField form field from stripping whitespaces when used for validation.
- Fix: Handle edge case that would generate a null exception.
- Fix: Only change loading state when an action method gets called, not on every event fire.

All changes since 0.9.1.

### v0.9.3

• Handle child elements triggering an event which should be handled by a parent unicorn element.

All changes since 0.9.1.

#### v0.9.1

• Fix: certain actions weren't triggering model values to get set correctly

All changes since 0.9.0.

### v0.9.0

- Loading states for improved UX.
- \$event special argument for actions.
- u unicorn attribute.
- APPS setting for determing where to look for components.
- Add support for parent elements for non-db models.
- Fix: Handle if Meta doesn't exist for db models.

All changes since 0.8.0.

#### v0.8.0

Add much more elaborate support for dealing with Django models.

All changes since 0.7.1.

### v0.7.1

- Fix bug where multiple actions would trigger multiple payloads.
- Handle lazy models that are children of an action model better.

All changes since 0.7.0.

### v0.7.0

- Parse action method arguments as basic Python objects
- Stop and prevent modifiers on actions

- Defer modifier on model
- Support for multiple actions on the same element
- Django setting to minimize the JavaScript

#### **Breaking changes**

- Remove unused unicorn\_styles template tag
- Use dash for poll timing instead of dot

All changes since 0.6.5.

### v0.6.5

• Attempt to get the CSRF token from the cookie first before looking at the CSRF token.

All changes since 0.6.4.

### v0.6.4

- Fix bug where lazy models weren't sending values before an action was called
- Add is\_valid method to component to more easily check if a component has validation errors.
- Better error message if the CSRF token is not available.

All changes since 0.6.3.

### v0.6.3

- Fix bug where model elements weren't getting updated values when an action was being called during the same component update.
- Fix bug where some action event listeners were duplicated.

All changes since 0.6.2.

### v0.6.2

- More robust fix for de-duping multiple actions.
- Fix bug where conditionally added actions didn't get an event listener.

All changes since 0.6.1.

#### v0.6.1

- Fix model sync getting lost when there is an action (issue 39).
- Small fix for validations.

All changes since 0.6.0.

#### v0.6.0

- Realtime validation of a Unicorn model.
- Polling for component updates.
- More component hooks

All changes since 0.5.0.

### v0.5.0

- Call component method from JavaScript.
- Support classes, dictionaries, Django Models, (read-only) Django QuerySets properties on a component.
- Debounce modifier to change how fast changes are sent to the backend from unicorn: model.
- Lazy modifier to listen for blur instead of input on unicorn: model.
- Better support for textarea HTML element.

All changes since 0.4.0.

### v0.4.0

- Set shortcut for setting properties.
- Listen for any valid event, not just click.
- Better handling for model updates when element ids aren't unique.

All changes since 0.3.0.

### v0.3.0

- · Add mount hook.
- · Add reset action.
- Remove lag when typing fast in a text input and overall improved performance.
- Better error handling for exceptional cases.

All changes since 0.2.3.

### v0.2.3

• Fix for creating default folders when running startunicorn.

All changes since 0.2.2.

### v0.2.2

• Set default template\_name if it's missing in component.

All changes since 0.2.1.

#### v0.2.1

• Fix startunicorn Django management command.

All changes since 0.2.0.

### v0.2.0

- Switch from Component class to UnicornView to follow the conventions of class-based views.
- Investigate using class-based view instead of the custom Component class

All changes since 0.1.1.

### v0.1.1

• Fix package readme and repository link.

All changes since 0.1.0.

#### v0.1.0

• Initial version with basic functionality.

### **FAQ**

### Do I need to learn a new frontend framework for Unicorn?

Nope! Unicorn gives you some magical template tags and HTML attributes to sprinkle in normal Django HTML templates. The backend code is a simple class that ultimately derives from TemplateView. Keep using the same Django HTML templates, template tags, filters, etc and the best-in-class Django ORM without learning another new framework of the week.

#### Do I need to build an entire API to use Unicorn?

Nope! Django REST framework is pretty magical on its own, and if you will need a mobile app or other use for a REST API, it's a great set of abstractions to follow REST best practices. But, it can be challenging implementing a robust API even with Django REST framework. And I wouldn't even attempt to build an API up from scratch unless it was extremely limited.

### Do I need to need to install GraphQL to use Unicorn?

Nope! GraphQL looks like an awesome technology for specific use-cases and solves some pain points around creating a RESTful API. But, it is another peiece of technology to wrestle with.

# Do I need to run an annoying separate node.js process or learn any tedious Webpack configuration incantations to use Unicorn?

Nope! Unicorn installs just like any normal Django package and is seamless to implement. There <em>are</em> a few "magic" attributes to sprinkle into a Django HTML template, but other than that it's just like building a regular server-side application.

# Does this replace Vue.js or React?

Nope! In some cases, you might need to actually build an SPA in which case Unicorn really isn't that helpful. In that case you might have to invest the time to learn a more involved frontend framework. Read Using VueJS alongside Django for one approach, or check out other articles about this.

# Isn't calling an AJAX endpoint on every input slow?

Not really! Unicorn is ideal for when an AJAX call would already be required (such as hitting an API for typeahead search or update data in a database). If that isn't required, the lazy and debounce modifiers can also be used to prevent an AJAX call on every change.

# But, what about security?

Unicorn follows the best practices of Django and requires a CSRF token to be set on any page that has a component. This ensures that no nefarious AJAX POSTs can be executed. Unicorn also creates a unique component checksum with the Django secret key on every data change which also ensures that all updates are valid.

### What browsers does Unicorn support?

Unicorn mostly targets modern browsers, but the project would appreciate any PRs to help support legacy browsers.

# How to make sure that the new JavaScript is served when a new version of Unicorn is released?

Unicorn works great with the whitenoise ability to serve static assets with a filename based on a hash of the file. CompressedManifestStaticFilesStorage works great for this purpose and is used by django-unicorn.com for this very purpose. Example code can be found at https://github.com/adamghill/django-unicorn.com/.

# What is the difference between Unicorn and lighter front-end frameworks like htmx or alpine.js?

htmx and alpine.js are great libraries to provide interactivity to your HTML. Both of those libraries are generalized front-end framework that you could use with any server-side framework (or just regular HTML). They are both well-supported, battle-tested, and answers to how they work are probably Google-able (or on Stackoverflow).

Unicorn isn't in the same league as either htmx or alpine.js. But, the benefit of Unicorn is that it is tightly integrated with Django and it should "feel" like an extension of the core Django experience. For example:

- redirecting from an action uses the Django redirect shortcut
- validation uses Django forms
- Django Models are tightly integrated into Unicorn (especially with the \$model special argument)
- you won't have to create extra URLs/views for AJAX calls to send back HTML because Unicorn handles all of that for you

Unicorn is a reactive component framework that progressively enhances a normal Django view, makes AJAX calls in the background, and dynamically updates the DOM. It seamlessly extends Django past its server-side framework roots without giving up all of its niceties or re-building your website.

# **Related projects**

Unicorn stands on the shoulders of giants, in particular morphdom which is integral for merging DOM changes.

# Inspirational projects in other languages

- Livewire, a full-stack framework for the PHP web framework, Laravel.
- · LiveView, a library for the Elixir web framework, Phoenix, that uses websockets.
- StimulusReflex, a library for the Ruby web framework, Ruby on Rails, that uses websockets.
- Hotwire, "is an alternative approach to building modern web applications without using much JavaScript by sending HTML instead of JSON over the wire". Uses AJAX, but can also use websockets.

# Full-stack framework Python packages

- Reactor, a port of Elixir's LiveView to Django. Especially interesting for more complicated use-cases like chat rooms, keeping multiple browsers in sync, etc. Uses Django channels and websockets to work its magic.
- Flask-Meld, a port of Unicorn to Flask. Uses websockets.
- Sockpuppet, a port of Ruby on Rail's StimulusReflex. Requires Django channels and websockets.
- Django inertia.js adapter allows Django to use <a href="https://inertiajs.com">inertia.js</a> to build an SPA without building an API.
- Hotwire for Django contains a few different repositiories to integrate Hotwire or its separate libraries into Django.

# Django packages to integrate lightweight frontend frameworks

• django-htmx which has extensions for using Django with htmx.

# Django component packages

- django-components, which provides declarative and composable components for Django, inspired by JavaScript frameworks.
- django-page-components, a minimalistic framework for creating page components and using them in your Django views and templates.
